REACH DESCRIPTION AND FISH UTILIZATION

This reach, which lies largely within the Athabasca River floodplain, is irregularly meandering and has many areas of unstable banks. Water levels and flow in at least the lower portion of this reach are affected by water level fluctuations in the Athabasca River. Gradient and water velocities in this section are the lowest in the studied portion of the Firebag River. Water flow is primarily swirling and a high proportion of the reach is composed of pools. The substrate is almost entirely fines. Although deciduous shrubs are an abundant component of the riparian vegetation, little of this growth overhangs the channel.

Northern pike, which were captured in this reach, and brook and ninespine stickleback, which were captured further upstream in the Firebag River, may spawn in the occasional grassy shallows along the banks within this reach. Adult lake whitefish, captured in this reach during autumn, may also spawn here. Although lake whitefish prefer to spawn over rocky substrates, they will spawn over sandy substrates. Several forage fish species (e.g., trout-perch and pearl dace) that spawn over sandy substrates were captured within other reaches of the Firebag River; they may spawn in this reach. The reach is considered to be a relatively good rearing area for fish because of the slow waters and the presence of log debris and grassy shallows within which young fish may take refuge. Log jams, overhanging banks, and the many deep pools provide excellent resting and feeding areas for adult fish of larger piscivores such as walleye and northern pike. The many pools and relatively deep water in the reach provide abundant overwintering areas for fish.

REACH DESCRIPTION AND FISH UTILIZATION

This reach is located above the Athabasca River floodplain and is irregularly meandering with some near-vertical cut banks up to 40 m high. Areas with unstable banks are common. Gradient and water velocities are greater than those in Reach 1 but lower than those in upstream reaches of the Firebag River. The water is moderately deep and although some rapids are present, pools comprise most of the total reach area. Flow character is mixed, with swirling, rolling and broken waters. Fines comprise the majority of the substrate. Coniferous and deciduous trees predominate in the riparian vegetation and there is no overhanging vegetation.

Lake whitefish and a few of the forage fish species captured in the Firebag River that spawn over sandy substrates may spawn in this reach. Limited spawning of other fish species that normally spawn over gravelly substrates may also occur. Because of the relatively low water velocities and presence of debris, the rearing potential for fish is considered to be moderate. During the spring, moderate numbers of young lake chub, longnose dace and white sucker were captured. The presence of these smaller fish suggests that there is at least some feeding potential for northern pike and walleye in this reach. The many pools and moderately deep waters provide resting and feeding areas for adults of larger fish and also provide good overwintering areas.

REACH DESCRIPTION AND FISH UTILIZATION

This section is a short, irregularly meandering reach. River banks are up to 40 m high and unstable areas are common. Water velocities and gradient are moderately high. Flow character throughout the reach is almost entirely rolling, and pools comprise about half of the total reach area. Larges (rubble and boulders) and gravels are dominant substrates. Deciduous trees form the dominant component of the riparian vegetation, and coniferous trees, deciduous shrubs and grasses are all present in smaller amounts. Some vegetation overhangs the river.

The potential of this reach for spawning is considered to be good or excellent for most fish that occur in the river, because it contains a diversity of substrate sizes, current velocities and water depths. Unidentified fish eggs, collected in late May, provided proof of spawning in the reach. Adults of arctic grayling and longnose sucker, both spring spawners, were captured in May. The combination of occasional grassy shallow backwaters, areas shaded by overhanging vegetation, and substrate composed of gravels and larges provides good rearing areas for most fish species in the river. Large numbers of young lake chub, white sucker and longnose sucker were captured in this reach. Most young forage fish prefer the quiet sheltered areas, whereas young arctic grayling prefer rocky substrates. The areas of overhanging riparian vegetation and the numerous pools provide good resting and feeding areas for larger fish. The high numbers of forage fish, particularly lake chub, provide a good food source for piscivorous fishes. Although there are many pools in this reach, the relatively shallow water depths may preclude overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

Due to river erosion of sand-clay and sand-bitumen cut banks, many of the river banks in this irregularly meandering reach are unstable. Water velocities and gradient are moderate. A high proportion of the reach is composed of pools, and the flow character is swirling throughout almost the entire reach. Larges (rubble and boulders) and gravels are dominant substrates. Deciduous trees dominate riparian vegetation, and grasses and deciduous shrubs overhang the channel. More debris is found in this reach than in any other surveyed in the Firebag River.

Because of the diversity of substrate sizes, current velocities and water depths, the spawning potential of this reach for most fish that are found in the river is considered to be good to excellent. Unidentified fish eggs were collected in gravelly shallows in late May and all adults captured in this reach in the spring were spent. Adult spring spawners captured here in the spring include arctic grayling, longnose sucker and walleye. Rearing potential for most young fish is considered to be good because of the presence of areas sheltered by overhanging vegetation, rocky substrates and moderate quantities of debris. Young lake chub and longnose dace were particularly numerous in this reach. The high number of pools and areas shaded by overhanging vegetation provide good feeding and resting areas for larger fish. Sheltered backwaters inhabited by forage fish, particularly lake chub, provide good feeding areas for walleye and northern pike. Although pools compose a high percentage of the total reach area, water depths are shallow and fish overwintering is probably limited to isolated deep pools.

REACH DESCRIPTION AND FISH UTILIZATION

This reach is essentially a riffle area. Only a relatively small proportion of the reach area is composed of pools, and waters are generally shallow. Areas of unstable river banks are numerous in this irregularly meandering reach. Moderate water velocities and gradient prevail in this reach and the flow character varies from swirling to rolling to broken. The substrate consists primarily of larges and gravels. Riparian vegetation is mostly deciduous trees, grasses and deciduous shrubs, some of which overhang the banks.

The diversity of water velocities, water depths and substrate sizes provide good spawning areas which are suitable for most fish species that are found in the Firebag River. Fine substrates are suitable for spawning of trout-perch and pearl dace and also possibly for spawning of lake whitefish. Grassy shallows in areas with fine substrates are suitable for northern pike spawning. All other species found in the river (including arctic grayling) may spawn over the substrates composed of gravels and larges. Unidentified fish eggs were collected from an area with rubble and gravel substrates in this reach. Areas sheltered by overhanging riparian vegetation, grassy shallows and sheltered backwaters provide good rearing areas for the young of most fish species in the river, and the abundance of gravel and rubble substrates is excellent for young arctic grayling. Relatively high numbers of young arctic grayling were captured in this reach. Backwaters sheltered by overhanging vegetation are suitable areas for most larger fish to rest and feed. The predominating riffle areas provide good feeding habitat for arctic grayling. Overwintering potential is limited to the few deep pools in the reach.

REACH DESCRIPTION AND FISH UTILIZATION

This section, the most upstream reach of the portion of the Firebag River that was surveyed, meanders irregularly and is primarily an extensive riffle zone with the occasional moving pool. The river banks are generally stable. This reach has the steepest gradient and highest water velocities encountered in the surveyed portion of the Firebag River. Waters are shallow and the flow character is rolling and broken. A relatively small proportion of the reach is pools. As in Reach 5, gravels and larges are the dominant components of the substrate material. Deciduous shrubs dominate riparian vegetation and overhang the channel in some areas.

The potential of this reach for spawning of both sport and forage fish is considered to be excellent. Numerous grassy side sloughs provide good spawning areas for northern pike and some forage fish. The many areas with rocky substrates are excellent spawning areas for arctic grayling and some species of forage fish. Walleye in the reach may spawn in a variety of areas. (Adult arctic grayling, northern pike and walleye were captured in the spring in this reach.) Rearing potential for sport fish is considered to be excellent; many young-of-the-year arctic grayling were captured in shallow gravel riffles, and young-of-the-year northern pike were captured in weedy areas with sandy substrates. The gravelly riffle areas should provide excellent feeding areas for arctic grayling, and northern pike and walleye can feed in the more placid backeddies and side sloughs. Fish probably overwinter only in the deeper backwaters of the reach.

REACH DESCRIPTION AND FISH UTILIZATION

A relatively short reach, this section flows in an irregular pattern and the river banks are relatively stable. Water velocities are the highest and gradient is the second highest recorded in the surveyed portion of the river. A low proportion of the total reach area is composed of pools. The flow character is primarily broken and tumbling, with occasional white-water rapids where the river flows over limestone ledges. Substrate composition is varied, with gravels and larges predominating. Deciduous trees and grasses dominate the riparian vegetation and there is a moderate amount of vegetation overhanging the channel.

The diversity of substrate types in this reach provides spawning areas which are probably suitable for many of the fish species found in the Marguerite River. Arctic grayling, mountain whitefish, suckers, and some of the minnows may spawn over the rocky substrates, and the remaining species may spawn over either the rocky or the sandy substrates. Adult arctic grayling and longnose suckers, both spring spawners, were captured here in the spring. The rocky substrates, moderate quantities of debris, and overhanging vegetation provide some rearing areas for several fish species. Young individuals of seven species were captured in this reach. Because of the relatively high water velocities and low number of pools, the resting and feeding potential for larger fish is considered to be low, although some larger fish may inhabit areas near the banks which are shaded by overhanging vegetation. Shallow water depths and the low number of pools preclude significant overwintering of fish in the reach.

REACH DESCRIPTION AND FISH UTILIZATION

This section is tortuously meandering and is essentially a long continuously swirling or placid pool. Gradient and water velocities are moderate. The substrate is mostly fines with some gravels. Coniferous and deciduous trees and deciduous shrubs are all important components of the riparian vegetation, and grasses are abundant. A moderate amount of vegetation overhangs the channel.

The predominating sandy substrates provide areas suitable for spawning of a few of the forage fish (e.g., trout-perch, pearl dace) found in the reach. Areas with gravelly substrates which may be suitable for spawning of the other species found in the river are limited. No adults were captured in this reach during the study. Rearing potential is considered to be poor to moderate; the moderate amount of overhanging vegetation and the small amount of debris provide the only suitable areas. Young lake chub were the most abundant fish collected. Moderate numbers of small forage fish and young of larger species captured in the reach provide a food source for piscivores, such as northern pike. Resting and feeding potential for larger fish is considered to be good to excellent because of the many pools in the reach. Overwintering potential is considered to be excellent because of the generally deep waters and large number of pools.

REACH DESCRIPTION AND FISH UTILIZATION

This reach is a short section which is almost entirely riffles. Gradient is the highest and water velocities the second highest in the surveyed portion of the Marguerite River. Substrate types are varied, with larges and fines being the most abundant. Coniferous and deciduous trees, deciduous shrubs, and grasses are all important components of the riparian vegetation and a fairly high proportion of the channel is covered by overhanging shrubs.

Because the reach contains a diversity of substrate sizes, current velocities, and water depths, spawning potential is considered to be good to excellent. The collection of unidentified fish eggs in late May provided proof of spawning in the reach. Rearing potential is considered to be good because of the rocky substrates, moderate quantities of debris, and the relative abundance of overhanging vegetation. Young of eight fish species were captured in this reach and slimy sculpin were especially abundant. Resting and feeding potential for larger fish is considered to be poor to moderate; the major suitable areas being those under overhanging vegetation. Relatively high water velocities and the low number of pools limit the resting and feeding potential for larger fish. Shallow water depths and the low number of pools probably preclude overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This is the longest of the reaches in the surveyed portion of the Marguerite River, and it is essentially a long, irregularly meandering placid pool. Water velocities and gradient are the lowest in the surveyed portion of the river. Most of the substrate in the reach is fines, but larges are present in some areas. Riparian vegetation is dominated by coniferous trees and deciduous shrubs and a relatively high proportion of the channel area is covered by overhanging vegetation. Large quantities of debris are present in this reach.

The substrate material in this reach is not suitable for spawning by the majority of the fish species captured in the reach. A few forage fish that normally spawn over sandy substrates would find ample suitable spawning areas in this reach. Large quantities of debris, an abundance of overhanging vegetation, and low water velocities provide good to excellent rearing areas in the reach. Very high numbers of young fish, particularly lake chub, were captured here in September. Excellent resting and feeding habitat for larger fish in the reach is provided by the many pools and areas sheltered by overhanging vegetation and debris. Piscivores have an abundant food supply in this reach. Although there are many pools in the reach, they may not be deep enough for fish to overwinter in.

REACH DESCRIPTION AND FISH UTILIZATION

This reach is the uppermost section of the surveyed portion of the Marguerite River. It is an irregularly meandering section with stable banks. Gradient and water velocities are moderate and the majority of the reach is riffles. The substrate is characterized by an abundance of larges mixed with fines and gravels. Deciduous trees are the dominant component of the riparian vegetation and a relatively high proportion of the channel is shaded by overhanging vegetation. As in Reach 4, large quantities of debris are present in this reach.

Although very few fish were collected in this reach during the study, conditions are considered to be excellent for spawning of most fish species in the Marguerite River because of the diversity of water depths, water velocities and substrate sizes. An abundance of debris, overhanging vegetation, and rocky substrate materials provides good to excellent rearing conditions for most fish. The potential for resting and feeding of larger fish is considered to be only fair; the few pools present and those areas shaded by overhanging vegetation would be most suitable. Shallow water depths and the relative paucity of deep pools limit overwintering potential in this reach.

REACH DESCRIPTION AND FISH UTILIZATION

This lower reach of the Muskeg River extends 0.5 km upstream from the confluence with the Athabasca River. It lies within the floodplain of the Athabasca River and is consequently influenced by fluctuations of water levels in that river. The gradient is moderately high, and although pools comprise the majority of the reach area, the presence of riffles is a prominent feature. There is a relatively high proportion of unstable banks. The substrate in most areas consists primarily of fines and gravels, but there are several areas with substrates containing substantial proportions of cobbles. The riparian vegetation is dominated by deciduous trees. Deciduous shrubs are also fairly abundant and some conifers are present. Little vegetation overhangs the river channel.

Although the sand and gravel substrates and the variety of water velocities in this reach would appear to provide areas suitable for spawning of several species of fish that occur in the Muskeg River (e.g., arctic grayling, longnose sucker, white sucker, trout-perch), most of these species are believed to spawn farther upstream in the Muskeg River. Rearing potential for most species is considered good; there are ample shallow backwater areas that provide suitable habitat. Juveniles and young-of-the-year of several species have been collected in this reach. The presence of forage species and young-of-the-year suckers in the mouth region of the Muskeg River would appear to provide good forage for piscivorous species. The mouth region may also be of some importance as a resting area during upstream migrations of some species (e.g., lake whitefish and walleye) in the Athabasca River. Water depths in this reach are generally shallow and may not be sufficient for overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This irregularly meandering section of the Muskeg River is entrenched in a deep, narrow canyon with a high proportion of unstable banks. The high, slumping banks appear to be composed primarily of sand, gravel and silt. The gradient is relatively high and the reach is a series of alternating pools and riffles. The substrate consists primarily of gravels and larges, but some sand and silt are present in pool areas. The riparian vegetation is dominated by deciduous trees and shrubs, but coniferous trees are also fairly abundant. Little vegetation overhangs the river channel in this reach. Moderate amounts of woody debris are present along the edges of the channel.

The series of pools and riffles and the variety of substrates in this reach provide excellent spawning potential for many of the fish species that occur in the Muskeg River (e.g., arctic grayling, white sucker, longnose sucker, longnose dace, lake chub, slimy sculpin, trout-perch). The numerous shallow areas along the sides of the channel, where water velocities are low and debris provides some shelter, are good rearing areas for a variety of fish species. The many shallow gravel riffles provide good feeding areas for juvenile arctic grayling. The pools of this reach are very good areas for resting and feeding of larger fish, and the variety of forage species provides an abundant food source for piscivorous species. Water depths in the pools are moderately deep and at least some pool areas may be suitable overwintering sites for some fish.

bedrock and/or oil sand	0
Debris	moderate

REACH DESCRIPTION AND FISH UTILIZATION

This relatively short and irregularly meandering section of the Muskeg River is a region of transition between the low gradient Reach 4 and the high gradient Reach 2. The gradient is moderate and the flow character is mixed, varying from placid to swirling to rolling. Most of the reach area is composed of pools. The substrate is composed mainly of sand, gravels and cobbles, but some silt is present in pools and backwaters. The riparian vegetation is mostly deciduous trees and shrubs, with some conifers in the lower portion of the reach. Some vegetation overhangs the channel in most areas. Moderate amounts of debris are present along the edges of the river channel.

The spawning potential of this reach is good for those species that spawn over gravel substrates (e.g., arctic grayling, longnose sucker, white sucker, trout-perch, longnose dace). There are a few backwater areas with low to moderate amounts of aquatic vegetation that may provide suitable habitat for limited spawning of northern pike and brook stickleback in this reach. The numerous shallow areas with low water velocities and gravel substrates, the occasional weedy shallows, and the moderate amounts of debris and overhanging vegetation provide good rearing habitat. In most areas of this reach the water is moderately deep, and at least some of the pools are probably suitable for overwintering of fish.

larges (>64 mm)	0
bedrock and/or oil sand	0
Debris	moderate

REACH DESCRIPTION AND FISH UTILIZATION

This long, low-gradient reach meanders through a large area of marshy treed muskeg. The reach is nearly all pools and the water flow is slow. The stream is deep and the banks drop off sharply at the edge of the channel. There are many beaver dams in this reach, particularly upstream from Hartley Creek. The substrate is entirely silt and sand with moderate to very high organic detritus content. Aquatic vegetation is abundant. The riparian vegetation is almost entirely deciduous trees and shrubs with a very dense growth of grasses. Channel cover due to overhanging shrubs varies from moderate in the lower portion of the reach to very high in the upper portion of the reach. Channel debris also varies from moderate to high.

The abundant aquatic vegetation in this reach provides numerous areas suitable for spawning of brook stickleback and northern pike. The reach does not appear to be suitable for spawning of other species. Rearing potential is good because there is ample shelter provided by woody debris and aquatic vegetation. Water depths in this reach appear to be sufficient to allow overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This section of the Muskeg River has a much higher gradient than does Reach 4. The reach is almost entirely pools, however, because the flow is impeded by numerous beaver dams. The substrate is generally sand and silt with moderate organic detritus content, but there are some areas with fairly high proportions of gravels and cobbles. Coniferous trees dominate the riparian vegetation over much of the reach, but deciduous trees and shrubs are also abundant and there is a dense growth of grasses. Channel cover is very high due to overhanging shrubs. Sunken woody debris is abundant.

Movement of the larger fish into this reach from downstream regions is severely limited by beaver dams. Only brook stickleback, lake chub, pearl dace, and a few young-of-the-year white suckers have been collected in this reach. The brook stickleback, lake chub, and pearl dace are almost certainly year-round residents of this reach.

NUMBERS OF FISH COLLECTED (SEPTEMBER 1979)

No fish collections were made in this reach.

PHYSICAL CHARACTERISTICS

Reach length (km)	19.0
Channel width (m)	8
Channel area (ha)	15.2
Gradient (m/km)	4.2
Flow character	placid
Total pools (%)	100
Pattern	irregularly meandering
Confinement	unconfined
Unstable banks (%)	0
Substrate composition (%)	
fines (<2 mm)	100
gravels (2-64 mm)	0
larges (>64 mm)	0
bedrock and/or oil sand	0
Debris	high

REACH DESCRIPTION AND FISH UTILIZATION

This section of the Muskeg River meanders in an irregular pattern through a very marshy region. Although the gradient is high, there are many beaver dams that reduce the flow, and the reach consequently consists entirely of placid pools. No sites were sampled in this reach, but it is expected that the substrate is probably sand and silt with a high organic detritus content. Riparian vegetation consists of deciduous trees and shrubs and a dense growth of grasses. The stream channel is almost completely covered by overhanging vegetation, and woody debris is abundant.

No fish collections were made in this reach. It is probable, however, that the habitat is suitable only for brook stickleback, which would be year-round residents of the area.

BENTHIC INVERTEBRATES

No benthic samples were taken in this reach.

REACH DESCRIPTION AND FISH UTILIZATION

This short, tortuously meandering reach extends upstream 4.5 km from the confluence of Hartley Creek and the Muskeg River. The gradient is relatively low and the reach is almost entirely pools with placid or swirling flow. The substrate is entirely silt and sand with a low organic detritus content. The riparian vegetation consists of deciduous trees and shrubs and a dense growth of grasses. Substantial amounts of shrubs overhang the stream channel throughout this reach. There is a moderate amount of debris in the channel.

Weedy areas along the banks provide good spawning habitat for brook stickleback and northern pike. The spawning potential of this reach for other species is considered poor. Some areas with sand substrates may be suitable for spawning of pearl dace and lake chub. The low water velocities and the abundant debris, overhanging vegetation, and aquatic vegetation along the banks provide good rearing conditions in this reach. The water is moderately deep throughout the reach and appears to be sufficient for overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This irregularly meandering section of Hartley Creek has a moderate gradient. Although the reach is mostly pools, riffle areas are fairly numerous. The flow character is mixed, varying from placid to swirling to rolling. There were several beaver dams present in this reach at the time the stream was surveyed in 1979. The substrate in most of the reach is sand with small amounts of silt; however, a number of areas (the riffle sections) do have gravelly and cobble substrates. Most quiet areas along the banks have some aquatic vegetation. The riparian vegetation is primarily deciduous trees and shrubs, but there are scattered patches of conifers. There is also a dense growth of grasses, and there is some overhanging vegetation throughout this reach. Moderate amounts of debris are present in the stream channel.

The sections of this reach with gravel and cobble substrates provide good spawning potential for a number of fish species (e.g., arctic grayling, longnose sucker, white sucker, longnose dace, slimy sculpin). The weedy shallow areas along the banks probably provide suitable spawning habitat for brook stickleback. The rearing potential of this reach is considered good because there are many areas with low water velocities and abundant shelter. The many deep pools in this reach are probably good for resting and feeding of larger fish. Water depths appear to be sufficient for overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This section of Hartley Creek meanders in a tortuous pattern through a marshy area. The gradient is low and the flow is generally placid or swirling. A high proportion of the reach consists of pools, but there are some small riffle areas. Several beaver dams were present in this reach at the time the stream was surveyed in 1979. Although the substrate in most of the reach consists of sand and silt, there are a few areas with gravel and cobble substrates. The riparian vegetation is dominated by deciduous trees and shrubs and some areas of coniferous trees are present. There is a very dense growth of grasses, and the channel cover due to overhanging shrubs is fairly high. Large amounts of woody debris are present in the stream channel.

The spawning potential of this reach for those species that require gravel substrates is considered poor. The only suitable locations are the few small riffle areas. Many areas with sand substrates are probably suitable for spawning of pearl dace, and the abundant aquatic vegetation provides suitable spawning habitat for brook stickleback. The low water velocities, the aquatic vegetation, and the large amounts of debris provide many areas that appear suitable for rearing purposes. Water depths in this reach appear to be sufficient to allow overwintering of fish.

larges (>64 mm)	0
bedrock and/or oil sand	0
Debris	high

REACH DESCRIPTION AND FISH UTILIZATION

This irregularly meandering section of Hartley Creek has a high gradient, and the flow character is mixed, varying from placid to swirling to rolling. Although the gradient is high, flow is impeded by the very many beaver dams, some of which are partially vegetated and appear to be very old. Because of the many beaver dams, the majority of the reach consists of pools. Some riffle areas are present immediately downstream from beaver dams. Substrates in most of the reach consist of silt and sand, but some gravel is present in the short riffle areas. The riparian vegetation is dominated by deciduous trees and shrubs in much of the reach, but coniferous trees are abundant in some areas. There are relatively small amounts of overhanging vegetation and large amounts of debris.

This reach is not considered to be suitable for spawning of most fish species; suitable substrates are extremely limited and the beaver dams severely limit movements of larger fish. There are many areas with abundant aquatic vegetation that are good spawning and rearing areas for brook stickleback. This species is undoubtedly a year-round resident in this reach.

Substrate composition (%)	
fines (<2 mm)	100
gravels (2-64 mm)	0
larges (>64 mm)	0
bedrock and/or oil sand	0
Debris	high

REACH DESCRIPTION AND FISH UTILIZATION

This section of Hartley Creek meanders in an irregular pattern through a very marshy area. Although the gradient is high, water flow is impeded by numerous beaver dams and the region is poorly drained. The reach consists entirely of placid pools. Although no sites were sampled in this reach, the substrate is believed to consist of sand and silt, and it probably has a high organic detritus content. The riparian vegetation is a mixture of coniferous trees, deciduous trees, and deciduous shrubs. There is also a very dense growth of grasses. A large proportion of the stream is covered by overhanging vegetation and there is a large amount of debris.

No fish collections were made in this reach. It is probable, however, that the habitat is suitable only for brook stickleback, which would be year-round residents of the area.

REACH DESCRIPTION AND FISH UTILIZATION

This short, lower reach of the Steepbank River lies within the Athabasca River floodplain and is affected by water levels in that river. Gradient is relatively high and there are a few areas of unstable banks. Flow character is primarily swirling and rolling and about half of the total reach area is composed of pools. Gravels and larges are the dominant substrate materials. Riparian vegetation is dominated by deciduous trees but conifers are also fairly abundant. There is no vegetation overhanging the river channel.

Spawning potential for fish that normally spawn over rocky substrates is excellent and there are also some areas that are suitable for fish that normally spawn over sandy substrates. Adults of several forage fish species were captured in this reach during the study. Rearing potential is considered to be moderate; the most suitable rearing areas in the reach are the spaces between large stones and rocks. Young slimy sculpin were particularly abundant in September. The moderately deep water and numerous pools in the reach provide suitable resting, feeding and overwintering areas for larger fish. There are numerous forage species and young of larger species in this reach that would serve as prey for piscivores (e.g., northern pike, walleye).

fines (<2 mm)	15
gravels (2-64 mm)	30
larges (>64 mm)	40
bedrock and/or oil sand	15
Debris	low

REACH DESCRIPTION AND FISH UTILIZATION

This irregularly meandering section of the Steepbank River is confined within deep (up to 60 m) canyon walls of the McMurray Oil Sands formation, and areas of unstable banks are numerous. Although gradient and water velocities are relatively high, about half of the area of this reach is composed of pools. The substrate is composed primarily of larges and gravels. Riparian vegetation is dominated by deciduous trees, but conifers are also fairly abundant. There is no vegetation overhanging the channel.

Because of the diversity of substrate sizes and water velocities and depths, the spawning potential is considered to be excellent, particularly for those species that prefer to spawn over rocky substrates. A relatively high number of adult arctic grayling were captured in this reach. The potential for rearing purposes is considered to be moderate, with the large rocky substrates providing the major suitable areas. The most abundant young fish captured during the study were slimy sculpin. This reach is rated as good for resting and feeding of larger fish because the water is relatively deep and pools are numerous. For similar reasons, overwintering potential is considered to be good.

REACH DESCRIPTION AND FISH UTILIZATION

This reach extends upstream from the near-vertical canyon walls of Reach 2 to the confluence of the Steepbank and North Steepbank rivers. This section flows in a sinuous pattern and the gradient is the highest recorded for the Steepbank River. Water velocity is generally high and flow character varies from swirling to rolling to broken. Pools compose a lower proportion of the reach than in other sections of the river. Substrates are composed primarily of gravels and larges. Coniferous trees are the dominant riparian vegetation and there is little vegetation overhanging the channel.

The diversity of substrate sizes, stream velocities, and water depths provides areas that should be excellent for spawning of most fish species found in the river, particularly those that require rocky substrates to spawn over. Arctic grayling adults netted here during this study were either developing or spent adults, and may have spawned in this reach. The grassy shallows present in this reach are excellent for spawning of northern pike and stickleback. Rearing potential for most fish is considered to be good because of the rocky substrates and grassy areas along the insides of bends where the water is shallow. Higher numbers of young fish were captured in the reach during this study than in other sections of the Steepbank River. The numbers of slimy sculpin were particularly high. Suitable areas for larger fish to rest and feed are found in the pools. Moderately deep waters and pools provide some overwintering potential for fish.

REACH DESCRIPTION AND FISH UTILIZATION

This short reach flows in a sinuous pattern and the gradient and water velocities are moderate. Approximately half of the reach area consists of pools. The river banks are stable. The substrate consists mainly of larges with smaller amounts of both fines and gravels. The riparian vegetation consists of a dense growth of grasses and a mixture of deciduous shrubs, deciduous trees and coniferous trees. Little vegetation overhangs the channel.

Spawning potential in this reach is excellent for those fish that require rocky substrates. There are also numerous areas that are suitable for fish that normally spawn over sandy substrates. Suitable rearing areas for many fish are found in the rocky substrates (young-of-the-year fish) and the few areas sheltered by overhanging vegetation (juvenile fish). Pools provide the major suitable resting and feeding areas for larger fish. Although pools are numerous in this reach, they are not particularly deep; therefore, overwintering potential may be limited.

REACH DESCRIPTION AND FISH UTILIZATION

This section of the Steepbank River is essentially a narrow, irregularly meandering pool with relatively placid waters. Both gradient and water velocities are the lowest recorded for the river, and water depths are somewhat greater than in other sections of the river. The river banks in this reach are stable. The substrate is almost entirely fines, with a very low proportion of gravels. Large amounts of debris and frequent log obstructions exist in the reach. Deciduous trees and shrubs are more abundant in the riparian vegetation than are conifers and grasses are very abundant. There is a moderate amount of overhanging vegetation.

Spawning potential for those fish that will spawn over sandy substrates (e.g., several minnows, trout-perch, coregonids, and goldeye) is good in this reach. Waters are probably sufficiently deep to allow burbot spawning in the winter under the ice (this species will spawn over sandy substrates). Grassy shallows in this reach are suitable for spawning of northern pike and stickleback. Because of the slow water velocities, grassy shallows, and the abundance of sheltered areas provided by debris, logs, and overhanging vegetation, the rearing potential for many fish is considered to be excellent. The many pools and areas sheltered by overhanging vegetation, debris, and logs provide excellent resting and feeding areas for larger fish. Overwintering potential is good due to the generally deep waters and numerous pools.

REACH DESCRIPTION AND FISH UTILIZATION

This wide lower reach of the MacKay River is within the Athabasca River floodplain and flows in a straight pattern. There are a few high slumping banks and many areas with unstable, undercut banks. Gravel bars are numerous and some sand bars are present at the mouth of the river. The gradient is moderate, and flow characteristics in the reach are almost entirely shallow, swirling pool conditions. The substrate consists primarily of gravels, with some areas of sand. Deciduous trees and shrubs dominate the riparian vegetation, but conifers are also fairly numerous and grasses are abundant. Very little vegetation overhangs the wide channel.

The gravel substrate in this reach possibly provides suitable spawning areas for some of the fish species present in the MacKay River (e.g., longnose sucker, white sucker, trout-perch). Some of the areas with sandy substrates and moderate currents may be suitable for spawning by a few of the forage fish species, particularly pearl dace. Because of the general lack of debris or other shelter, this area is not considered to provide good rearing habitat. Although the mouth area may provide a resting area for fish migrating upstream in the Athabasca River, the potential for resting and feeding of adult fish is considered poor in the majority of the reach because there is little shelter and water depths are shallow. The shallow water probably precludes overwintering of fish in this reach.

bedrock and/or oil sand	5
Debris	low

REACH DESCRIPTION AND FISH UTILIZATION

This short reach lies just above the Athabasca River floodplain and flows in a sinuous pattern through a narrow valley. The steep valley walls are 40 to 50 m high and there are several areas with high, near-vertical, slumping banks. The gradient is moderate and the reach consists almost entirely of swirling pools. The substrate consists of gravels with some sandy areas. Riparian vegetation is primarily deciduous trees and shrubs with some stands of conifers. Grasses are also abundant.

This reach provides many areas that should be good for spawning of those fish species that require gravel substrates. Arctic grayling, longnose sucker, white sucker and trout-perch have all been collected in the lower reaches of the MacKay River and all spawn over gravel substrates. Rearing potential is considered fair; some grassy shallow areas provide the only suitable habitat. Because of the relatively deep water and the many pools, the potential for adult fish resting and feeding is considered good. The deep pools also provide several good areas for overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This tortuously meandering section is entrenched within a canyon that is cut 40 to 50 m deep into the McMurray Oil Sands formation. There is a very high proportion of unstable banks, which are primarily high, near-vertical, slumping areas. Exposed oil sands deposits are common, and a film of oil on the water surface is visible from the air in many places. Gradient and water velocities are moderate, and there are numerous riffle areas in addition to many relatively deep pools. The substrate consists primarily of gravels and larges with oil sand being a major component of the substrate in many places. The riparian vegetation is dominated by deciduous trees and shrubs and there are scattered patches of conifers. Very little vegetation overhangs the banks.

Several areas, where the substrate is primarily gravel, appear suitable for spawning of a number of fish species (e.g., arctic grayling, longnose sucker, white sucker, trout-perch). Suitable rearing areas for young-of-the-year of many species are provided by the numerous shallow areas with slow currents and gravel and rock substrates. Adults and juveniles of most fish species that occur in the MacKay River have been collected in this reach. The numerous pools of this reach provide good resting and feeding areas for adult fish and the abundance of forage fish species and young of other species provides good feeding potential for piscivores. The water depths in many of the large pools in this reach are probably sufficient to allow overwintering by fish.

bedrock and/or oil sand	0
Debris	low

REACH DESCRIPTION AND FISH UTILIZATION

This irregularly meandering section is confined by the valley walls, but evidence of lateral channel movement (i.e., oxbows and meander scars) within the valley is present. The banks on the outside of bends in the river are often steep and slumping, but the proportion of the banks that are unstable is much less than in Reach 3. The gradient in this reach is steeper than in Reach 3 and water velocities are relatively high. Pools comprise a little over half of the reach area and are generally shallow. The substrate in this reach consists primarily of larges and coarse gravels, with sand and silt present in the pools. Although the riparian vegetation is mostly deciduous trees and shrubs, some patches of conifers are present and grasses are abundant.

The gravel substrates and many riffles in this reach provide areas that are excellent for spawning of arctic grayling, longnose sucker, white sucker, longnose dace and trout-perch. Those areas with large rocks and slower currents are probably suitable for spawning of lake chub and slimy sculpin. The rearing potential of this reach is considered good because areas with large rock substrates provide adequate shelter. Areas suitable for resting and feeding of adult fish are provided by the numerous pools in this reach. Because forage fish are abundant in this reach, feeding potential for piscivorous species is considered good. Because the pools in this reach are relatively shallow, overwintering of fish is probably not possible except in isolated deep pools.

Debris	low

REACH DESCRIPTION AND FISH UTILIZATION

This long, irregularly meandering section has a relatively high gradient and is essentially a series of riffles. The proportion of the reach area that consists of pools is the lowest in the surveyed portion of the MacKay River, and the flow character varies from swirling to rolling to broken. Areas with unstable banks are fairly common but are less frequent here than in the four lower reaches of the river. The substrate is almost entirely larges and gravels, with some sandy areas in quiet shallows along the banks. Coniferous trees are a dominant component of the riparian vegetation and deciduous trees and shrubs are also numerous. There is usually a dense growth of grasses along the banks and very little overhanging vegetation.

Although the spawning potential of this reach is considered good for arctic grayling, suckers, longnose dace and slimy sculpin, high water velocities and the large sizes of the substrate materials may limit spawning over much of the reach. The rearing potential of this reach is considered moderate; shelter is provided by large rocks in shallow areas along the banks and there are few grassy shallows. Because there are relatively few pools and the water is generally shallow and swiftly flowing, the resting and feeding potential for adults of the larger species is relatively poor. However, the many riffle areas should provide good feeding habitat for arctic grayling. The water depths in most of this reach are probably not sufficient for overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This section of the MacKay River has a much lower gradient than Reach 5 and meanders in an irregular pattern. Most of the reach consists of pools with placid or swirling flow, but there are a few riffle sections. Several beaver dams were present in this reach at the time the river was surveyed in 1979. The substrate consists primarily of fines and small gravels with some cobbles and boulders. Coniferous trees dominate the riparian vegetation over much of the reach, but deciduous trees and shrubs are also abundant and there is a dense growth of grasses in most places. There is a large amount of debris in the channel.

For most of the larger fish species, the spawning potential of the reach is poor. There are many areas, however, that are probably suitable for spawning of some forage fish species that spawn over sand or silt substrates. Some northern pike may also spawn in this reach. The rearing potential of this reach is considered very good; shelter is provided by abundant debris in shallow pool areas and there are some weedy shallows. The many deep pools and abundant debris provide good resting and feeding areas for adults of some of the larger fish species, particularly suckers and northern pike. The water depths over much of the reach are probably sufficient to allow overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This uppermost reach of the surveyed portion of the MacKay River meanders in a tortuous pattern through a marshy area of treed muskeg. Several beaver dams were present at the time the river was surveyed in 1979. The gradient is very low and the flow is sluggish through the entire reach. The substrate consists of silt and clay with organic detritus. Aquatic vegetation is abundant, and there is a large amount of debris in the channel. The riparian vegetation is dominated by deciduous shrubs and a very dense growth of grasses. Deciduous trees are also numerous and there are some patches of conifers.

The abundant aquatic vegetation in this reach provides excellent spawning habitat for northern pike and brook stickleback. The reach does not appear to be suitable for spawning of other species. The large amount of debris and aquatic vegetation in this reach provides suitable rearing habitat for some species (e.g., brook stickleback and northern pike) and the water depth in this reach appears to be sufficient to allow overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This lower reach of the Dover River is a high gradient section that extends upstream 12.5 km from the confluence with the MacKay River. The river channel is irregularly meandering, and there is a relatively high proportion of unstable banks that consist of silt, sand and gravel. Several beaver dams were present at the time the river was surveyed in 1979. Although the gradient in this reach is relatively high and riffles are numerous, water velocities in most of the reach are moderate and a high proportion of the reach consists of pools. The substrate consists primarily of larges and coarse gravels, but there are areas with sand and fine gravel substrates. The riparian vegetation is mostly deciduous trees and shrubs, with some patches of coniferous trees. There is a relatively dense growth of grasses and little overhanging vegetation. A moderate amount of debris is present in the river channel.

The spawning potential of this reach is considered good for several species of fish that have been collected from the Dover River. The numerous riffle areas provide suitable spawning locations for some species that spawn over gravel substrates (e.g., white sucker, longnose dace). Other areas with sand and fine gravel substrates may be suitable for spawning of some of the forage fish, particularly pearl dace. Numerous shallow backwaters and the abundant shelter provided by debris and some aquatic vegetation provide very good rearing potential in this reach. Good resting and feeding locations for larger fish are provided by the numerous swirling pools. There are a number of moderately deep pools that are probably suitable for overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This short reach is a region of transition between Reach 3, which has a low gradient, and Reach 1, which has a steep gradient. The river channel meanders in an irregular pattern and there are a few areas with high, unstable banks. These banks appear to be composed of silt, sand and gravel. Exposed oil sands deposits are also evident in some places. Although the gradient is moderate, the flow is mostly placid and slow due to the large number of beaver dams in this reach. There are high proportions of silt and sand in the substrate, but gravels and larges are also abundant, particularly downstream from beaver dams. The riparian vegetation is dominated by deciduous trees and shrubs, but there are some scattered patches of conifers. Grasses are abundant and there is some overhanging vegetation in most areas. There is a moderate amount of debris in the river channel.

The potential of this reach for spawning of the larger fish species is considered low; suitable substrates and riffle areas are not abundant, and the beaver dams probably severely limit upstream movement of the larger fish. The small gravelly areas downstream from beaver dams may be suitable for spawning of some forage fish species (e.g., pearl dace, trout-perch, slimy sculpin). Some suckers may also spawn in this reach. The shallow backwaters, abundant debris, and overhanging vegetation provide very good rearing habitat, and the deep beaver impoundments are suitable overwintering areas for forage fish and possibly suckers.

REACH DESCRIPTION AND FISH UTILIZATION

This section of the Dover River meanders in an irregular pattern through an area of treed muskeg. The gradient is low and the reach is virtually all placid pools. Beaver dams are very numerous. The substrate is almost entirely sand and silt with some organic detritus, but there are some small areas with gravel substrates immediately downstream from beaver dams. The river banks are stable and well vegetated. The riparian vegetation is dominated by deciduous shrubs and a dense growth of grasses. Deciduous trees are also numerous, but only scattered patches of conifers are present. In most areas, some grasses and shrubs overhang the river channel. Debris in the river channel, most of which appears to be the result of beaver activity, is moderate.

Because the numerous beaver dams are certain to severely limit the movement of larger fish and because areas with gravel substrates are few, the spawning potential for most of the larger fish species is considered to be poor. There are many areas, however, that appear to be suitable for spawning of those forage fish that will spawn over sandy substrates (e.g., pearl dace, trout-perch). Some spawning of suckers may also occur in this reach and the moderate amounts of aquatic vegetation may provide some spawning areas for brook stickleback and northern pike. The numerous weedy shallows, abundant debris, and overhanging vegetation provide good rearing areas in this reach. Juvenile northern pike, trout-perch and white sucker were collected here. The deep ponds formed behind beaver dams provide good overwintering areas.

REACH DESCRIPTION AND FISH UTILIZATION

This tortuously meandering reach has a low gradient similar to that of Reach 3, and the entire reach consists of slowly flowing pools. Beaver dams are numerous, although not as abundant as in Reach 3. The stream is fairly deep and the banks are undercut and stabilized by vegetation. The substrate consists of silt and sand throughout much of the reach, but areas with sand and fine gravel substrates are fairly numerous. The riparian vegetation consists of deciduous shrubs and trees with scattered patches of conifers. There is also a dense growth of grasses. Shrubs and grasses overhang the river channel throughout the reach and there are large amounts of debris in the channel.

The areas with sand and gravel substrates in this reach may provide suitable spawning areas for several of the forage fish species that have been collected here (e.g., lake chub, pearl dace, trout-perch, slimy sculpin). Longnose suckers and white suckers have been collected in this reach and some spawning of these species may also occur in the reach. Several areas with low to moderate amounts of aquatic vegetation are probably suitable for spawning of brook stickleback. The large amounts of debris, undercut banks, and overhanging vegetation provide abundant rearing areas. The water depth is probably sufficient to allow overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This section of the Dover River meanders in a tortuous pattern through an area of muskeg. The gradient is fairly low, but somewhat steeper than the gradient in Reaches 3 and 4. Beaver dams are fairly numerous and the reach is entirely pools. The river banks are undercut, but are stabilized by vegetation. The substrate is almost entirely silt and sand, with only a few small areas of sand and gravel. Organic detritus is also abundant in the substrate material. The riparian vegetation consists of a mixture of deciduous trees, coniferous trees, and deciduous shrubs. There is also a dense growth of grasses. Much of the river channel is covered by overhanging shrubs and trees. There are large amounts of woody debris in the channel and many places where dead trees have fallen into the water.

This reach does not contain areas suitable for spawning of most fish species that occur in the Dover River. There are some areas with aquatic vegetation that may be suitable for brook stickleback spawning. Pearl dace may also spawn over some of the sandy substrates in this reach. The rearing potential is good due to the large amounts of debris, undercut banks, and abundant overhanging vegetation. Water depths are probably sufficient for overwintering of fish.

bedrock and/or oil sand	0
Debris	moderate

REACH DESCRIPTION AND FISH UTILIZATION

This reach is a long marshy section in a muskeg region. The gradient is low and the stream flow is very slow. Many beaver dams are present throughout this reach. The substrate consists almost entirely of sand, silt, and organic detritus, but there are a few areas with fine gravel substrates. The riparian vegetation is primarily grasses and deciduous shrubs, but there are also some deciduous and coniferous trees. There is a relatively large amount of overhanging vegetation and moderate amounts of debris in the river channel.

The abundant aquatic vegetation in this reach provides good spawning potential for brook stickleback and possibly northern pike (only brook stickleback were collected from this reach). Spawning potential for other species is considered poor, but some forage species (e.g., pearl dace) may be able to spawn successfully in this reach. Rearing potential is considered good because ample cover is provided by log debris and aquatic vegetation. Water depths are probably sufficient to allow overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

This lower reach of the Dunkirk River is a tortuously meandering section that flows through an area of treed muskeg. The gradient is very low and the entire reach is a placid pool area. The substrate consists of sand and silt with a fairly high content of organic detritus. Deciduous shrubs and trees dominate the riparian vegetation, but conifers are also abundant in some areas. There is also a very dense growth of grasses. Shrubs and grasses overhang the river channel throughout most of the reach. Debris in the river channel is abundant and there are many locations where trees have fallen into or across the river.

Aquatic vegetation is fairly abundant in this reach and provides very good spawning habitat for northern pike and brook stickleback. The spawning potential for other species is poor, but some forage fish species that will spawn over sandy substrates may spawn successfully at some locations in this reach. Low water velocities, and the ample shelter provided by debris and aquatic vegetation create an excellent rearing habitat for northern pike, brook stickleback, and other forage species. The presence of juvenile white suckers indicates that the area is also suitable for rearing of that species. Water depths appear to be sufficient to allow overwintering of fish in at least the lower portion of the reach.

REACH DESCRIPTION AND FISH UTILIZATION

This irregularly meandering section of the Dunkirk River has a slightly steeper gradient than Reach 1. Although most of the reach consists of pools with placid and swirling flow, there are some riffle areas. Beaver dams are fairly numerous in this reach. The substrate consists mainly of sand and gravel with some cobbles and boulders. Towards the upper end of the reach, the substrate is composed of more silt and sand and less gravel than in the lower portion of the reach. The river banks are generally stable and well vegetated. The riparian vegetation is a mixture of coniferous trees, deciduous trees, and deciduous shrubs. There is also a dense growth of grasses. Moderate amounts of shrubs and grasses overhang the river channel and there are large amounts of woody debris in the channel.

The gravel and sand substrates present in this reach provide areas that appear to be suitable for spawning of arctic grayling, longnose sucker, white sucker, slimy sculpin, lake chub, trout-perch, and pearl dace. The rearing potential of this reach is very good, due to the many areas with low water velocities and abundant shelter (provided by debris and some aquatic vegetation). The pools in this reach are moderately deep and many of them are probably suitable for overwintering of fish.

Debris	moderate

REACH DESCRIPTION AND FISH UTILIZATION

This uppermost reach of the surveyed portion of the Dunkirk River meanders in an irregular pattern through a marshy muskeg region. The gradient is very low, the stream channel is deep, and the water flow is slow. The substrate is entirely silt with a high organic detritus content. Aquatic vegetation is abundant. The riparian vegetation consists primarily of deciduous trees and shrubs, but patches of coniferous trees are also fairly numerous. Fairly large amounts of shrubs and grasses overhang the river channel throughout the reach. Moderate amounts of debris are present in the channel.

The abundant aquatic vegetation in this reach provides many areas suitable for spawning of northern pike and brook stickleback. The reach does not appear to be suitable for spawning of other fish species. Rearing potential is good because of the low water velocities, the shade provided by overhanging vegetation, and the ample shelter provided by woody debris and aquatic vegetation. Water depths in this reach appear to be sufficient to allow overwintering of fish.

REACH DESCRIPTION AND FISH UTILIZATION

Much of this short, tortuously meandering section of the Ells River lies within the Athabasca River floodplain. The gradient is fairly low and the entire reach is a pool with either placid or swirling flow. In most areas of the reach, the water is relatively deep. The substrate material is entirely fines. The riparian vegetation is dominated by deciduous trees and shrubs, but some conifers are present. There is also a fairly dense growth of grasses. None of the bank vegetation overhangs the channel.

Spawning potential for those fish species that usually spawn over sandy substrates is considered to be excellent. No suitable spawning areas exist for species that require gravel substrates. Very few areas within this reach are suitable for fish rearing. The slow water velocities may permit young fish to inhabit waters within the reach, but there are only a limited number of areas that provide suitable shelter. Resting and feeding potential for larger fish is considered to be moderate to good because the reach is essentially a deep continuous pool. However, there are few areas that provide any shelter. Because of the generally deep water and extensive pools, the overwintering potential of this reach is considered to be excellent.

Debris	moderate

REACH DESCRIPTION AND FISH UTILIZATION

This relatively short, irregularly meandering reach lies above the Athabasca River floodplain. The gradient is relatively low and this entire section of the river consists of deep pools with placid and swirling flow. The substrate is composed primarily of fines, but a few areas contain gravels. Deciduous trees and shrubs are the dominant components of the riparian vegetation, but some patches of conifers are also present. Little vegetation overhangs the channel.

Most areas within the reach provide suitable spawning grounds for those fish that normally spawn over sandy substrates. Only a few areas are suitable for spawning by those fish that prefer gravel substrates. Rearing potential in this reach is considered to be moderate; slow water velocities and moderate quantities of debris provide suitable rearing areas. Moderate numbers of young-of-the-year and juvenile fish, particularly lake chub, were captured in this section of the river during the study. Resting and feeding potential for larger fish is considered to be good to excellent because of the many deep pools and areas sheltered by debris. There is a variety of smaller fishes in this reach that may serve as prey for piscivorous species such as walleye and northern pike. Overwintering potential is considered to be excellent because of the deep pools.

REACH DESCRIPTION AND FISH UTILIZATION

This section of the Ells River is entrenched within a narrow deep canyon and meanders in an irregular pattern. Although the gradient is high and riffle sections are numerous, a relatively high proportion of the reach is composed of pools. The flow character is mixed, varying from swirling to rolling to broken, and water depths are generally shallow. Substrate composition is varied; larges predominate, but gravels and fines also compose substantial proportions of the substrate. The riparian vegetation is a mixture of coniferous and deciduous trees; deciduous shrubs are also fairly abundant. A small amount of vegetation overhangs the channel.

Because of the diversity of substrate materials and water velocities and depths, spawning potential in this section of the river is considered to be excellent for most fish species that occur in the Ells River. Suitable areas for the rearing of fish include the rocky substrates, a few areas sheltered by overhanging vegetation, and the scattered grassy shallows. Moderate numbers of young fish, particularly lake chub, were captured in this reach during the study. The numerous pools and the few areas shaded by overhanging vegetation provide good resting and feeding potential for larger fish. Although a large proportion of the reach is composed of pools, only a few of these areas are deep enough to provide suitable overwintering areas for fish.

REACH DESCRIPTION AND FISH UTILIZATION

This reach is a tortuously meandering section of the Ells River, with a relatively low gradient and swirling and rolling flow. Most of the reach is composed of pools and the water is moderately deep. The substrate consists primarily of larges and gravels, but sand and silt substrates are present in some areas. Riparian vegetation is mostly deciduous trees, but scattered coniferous trees are present. There is a relatively small amount of overhanging vegetation.

Spawning potential in this section of the river is considered to be excellent for those fish that normally spawn over rocky substrates, and moderate for those that normally spawn over sandy substrates. Numerous backwater pools, weedy sheltered areas alongside the river bank, areas shaded by overhanging riparian vegetation, and rocky substrates provide excellent rearing opportunities for most fish species found in the Ells River. Very high numbers of young fish, particularly lake chub, were captured in this section of the river during the survey. Resting and feeding potential for larger fish is considered to be excellent because of the many pools and the areas along the banks that are sheltered by overhanging vegetation. There appears to be an abundant food supply for piscivorous fish. Particularly large numbers of smaller fish were collected in this reach. Overwintering potential is rated as moderate to good; the many pools provide suitable areas for larger fish.

REACH DESCRIPTION AND FISH UTILIZATION

This section is a short, irregularly meandering reach that is essentially a series of riffles. Although gradient and water velocities are relatively high, there is a moderate number of pools. Water depths are fairly shallow over most of the reach. Substrates are predominantly larges and gravels, but there are also numerous areas with sandy substrates. Deciduous trees and shrubs comprise the major part of the riparian vegetation, and there is a small amount of vegetation that overhangs the channel. There is a moderate amount of debris in this reach.

The diversity of substrate sizes, current velocities and water depths provides excellent spawning potential for most fish species that occur in the Ells River, particularly for those fish that prefer to spawn over rocky substrates. Rearing potential is considered to be good because the moderate quantities of debris and the rocky substrates provide suitable shelter. Some areas along the banks that are shaded by overhanging vegetation are also suitable rearing areas. Suitable resting and feeding areas for larger fish are found in some of the areas sheltered by overhanging vegetation and debris. However, only a few backwater pools and eddies in the reach provide sufficiently deep waters for larger fish; resting and feeding potential for these fish is therefore considered to be poor. Shallow water depths and the paucity of deep pools preclude significant overwintering of fish in this reach.

REACH DESCRIPTION AND FISH UTILIZATION

This section is a long, tortuously meandering reach with a moderate gradient. It is a series of alternating pools and riffles, and just over half of the reach area is composed of pools. Water depths are relatively shallow over most of the reach. Substrates are varied, depending on location in the reach, and consist of larges, gravels and fines. The riparian vegetation is dominated by deciduous trees and shrubs, but grasses and significant numbers of conifers are also present. There is somewhat more overhanging vegetation in this section than in other reaches in the surveyed portion of the river.

Because of the variety of habitats provided by the long series of pools and riffles, the spawning potential of this reach is considered to be excellent for fish that normally spawn over rocky or sandy substrates. Adults of several species that spawn in the spring were captured here in May and June during this study. Areas sheltered by overhanging bank vegetation and debris and areas with rocky substrates provide excellent rearing habitat for many fish species. Very high numbers of young fish, particularly lake chub, were captured in the reach during this study. Overhanging vegetation, moderate quantities of debris, and numerous pools provide good resting and feeding areas for larger fish, particularly the piscivorous species. Overwintering potential for fish is considered to be moderate; many of the pools are probably too shallow to provide suitable over-wintering areas.

REACH DESCRIPTION AND FISH UTILIZATION

This section is a short, irregularly meandering reach that is predominantly broken riffles and white water rapids. Both the gradient and the water velocities are the highest recorded within the surveyed portion of the Ells River. The average water depth is shallow. Larges and gravels are the predominant substrate materials, but fines are also found in numerous areas within the reach. Deciduous trees and shrubs are the most abundant vegetation types along the river bank, but coniferous trees also comprise a significant proportion of the riparian vegetation. A small amount of vegetation overhangs the channel.

The diversity of water depths, water velocities, and substrate sizes in this reach provides a number of areas that may be suitable for spawning of several species of fish, particularly those that normally spawn over rocky substrates. In many areas, however, the water velocities may be too high for spawning to occur. Moderate quantities of debris and rocky substrates provide moderate to good rearing areas for most fish species, but high water velocities throughout most of the reach may limit the rearing potential. Resting and feeding potential for larger fish is considered poor to fair. Some overhanging vegetation and moderate quantities of debris provide a number of sheltered areas, but very few pools exist for larger fish to inhabit. The generally shallow water depths and the limited number of pools preclude significant overwintering of fish in this reach.

REACH DESCRIPTION AND FISH UTILIZATION

This section is the most upstream reach of the surveyed portion of the Ells River. The gradient is relatively high and the flow character is mixed, varying from swirling to rolling to broken. Approximately half of the total reach area is composed of pools and the water is moderately deep in many areas. Large rocks and boulders are the dominant substrate materials, but significant amounts of gravels and fines are also present. The riparian vegetation consists primarily of deciduous trees and shrubs, with some scattered conifers. There is a small amount of overhanging vegetation.

The spawning potential of this reach is considered to be excellent for many of the fish species that occur in the Ells River, because of the diversity in substrate sizes, water velocities and water depths. The reach is a particularly attractive spawning area for those fish that prefer rocky substrates. Rocky substrates and moderate quantities of debris provide good to excellent rearing opportunities for most fish species found in the Ells River. Some areas along the banks that are shaded by overhanging vegetation also provide suitable rearing habitat. Moderately high numbers of young fish, particularly white and longnose suckers, were captured in the reach during this study. Resting and feeding potential for larger fish is considered to be good, because of the numerous pools and areas sheltered by debris. Suitable overwintering areas are found in the numerous, relatively deep pools.
